ABSTRACT

Bioactive glass (BG) finds limited use as a bone replacement material owing to its low mechanical properties. In order to solve this problem, the micro-sized 13-93 BG was prepared as a fabric composite with SiC microfibers, and its mechanical properties and biocompatibility were investigated in this study. The tensile strengths of BG-SiC fiber-bundle composites increased in proportion to the number of SiC fibers. In particular, even when only one SiC fiber was substituted, the tensile strength increased by 81% to 1428 MPa. In the early stage of the in-vitro test, a silica-rich layer was formed on the surface of the 13-93 BG fibers. With time, calcium phosphate grew on the silica-rich layer and the BG fibers were delaminated. On the other hand, no products were observed on the SiC fibers for 7 days, therefore, SiC fibers are expected to maintain their strength even after transplantation in the body.

Key words: Bioactive glass, Bioglass-SiC fabric composite, Mechanical properties, Biocompatibility, Biomedical applications

1. Introduction

There is increasing interest in ceramic materials for human body insertion treatment related to aging and health. Further, the importance of organic-inorganic composites and porous bioceramic materials is increasing, considering the need for biocompatibility between materials and the living tissues in the human body.

Porous biocermics promote biological reactions, however, they cannot maintain the mechanical properties. This issue is hard to overcome physically as there exists a technical contradiction between the simple physical properties. In order to simultaneously realize high porosity, biocompatibility, and mechanical properties, it is necessary to graft materials and design them at the same time. It is expected that the above problem can be solved if a fabric can be made of bioactive glass (BG) fiber and a high toughness bio-inert fiber material.

BG was first developed by Hench of England in the early 1970s and commercialized owing to its excellent biocompatibility. The advantages of BG are it is tissue-friendly and does not induce the formation of fibrous tissue around it. In addition, CaO and P2O5 are present in BG, so that the surface is efficiently dissolved and hydroxyapatite (HAP) can be easily formed. BG is applied to coating materials, 3D scaffolds, dental materials, and charging materials for promoting bone formation, like HAP. However, BG has limited applicability owing to its low mechanical properties, despite its biocompatibility. In this context, various composite materials in the forms of coatings, fillers, and whiskers have been considered to solve this problem. However, these materials could not address the contradiction of high porosity and high strength.

Therefore, we fiberized BG and fabricated it in a porous and flexible form. In addition, it was expected that the mechanical properties would be enhanced by combining a biologically inert fiber material and the BG fiber. Silicon carbide (SiC) was selected as the material to be used as a fabric composite with BG. The chemical inertness of SiC suggests high resistance to corrosion in harsh environments such as body fluids. In addition, its high modulus of elasticity and low coefficient of friction render SiC an ideal material for smart implants and biosensors in vivo.

In this study, the BG-SiC fabric composite was prepared and the changes in the mechanical properties according to the proportion of SiC fibers was selected. The biocompatibility of the BG-SiC fabric composites was investigated by identifying the crystalline phase present on the surface after reacting with a simulated body fluid (SBF).

2. Experimental Procedure

2.1. Fabrication of BG fibers and BG-SiC fabric composite

In this study, the 13-93 BG composition (53 SiO2, 4 P2O5, 20 CaO, 5 MgO, 6 Na2O, 12 K2O, all in wt%) was selected. Its glass transition temperature (Tg), dilatometric softening temperature (Tsl), and half sphere temperature (T1/2) are
598.14°C, 641.3°C, and 1154°C, respectively. Fig. 1 is a schematic of a melt-spinning system.

This cullet was placed in a Pt-10%Rh crucible equipped with a single nozzle with a diameter of 2 mm, and the glass was fiberized at 1295°C. The fiberizing temperature was experimentally determined by trial and error. Winding was performed by varying the winding force and the number of rotations within the ranges 47.6-430 N and 50-150 rpm, respectively. The 13-93 BG fiber length produced under each condition was over 20 m. The fiber diameter was measured for each condition. A fabric composite of dimensions 30 × 30 mm was fabricated from the BG fiber and amorphous SiC fiber.

2.2. Measurement of the tensile strengths of BG fibers and BG-SiC fiber composite

The tensile strength was measured to evaluate the mechanical properties of 13-93 BG single fiber and 13-93 BG-SiC fiber-bundle composites. The test was carried out in accordance with ASTM standard D3379. A universal material testing machine (INSTRON 5544, INSTRON, USA) was used. The measurement conditions were a load cell capacity of 10 KN, a cross-head speed of 0.5 mm/min, and a gage length of 20 mm. The 13-93 BG-SiC fiber composite was a bundle that consisted of 10 BG and SiC fibers in total. The tensile strength was measured by controlling the number ratio of each fiber. The diameters of the two fibers were kept constant in the range 16–20 μm.

2.3. In-vitro testing of BG-SiC fabric composite

For the evaluation of the bioactivity of the 13-93 BG and SiC fibers, an in vitro test was conducted by using a SBF

solution. Table 1 shows the ionic concentrations of the SBF solution and human blood plasma. The test was performed in the static state by using a thermo-hygrostat maintained at a temperature of 36.5 ± 1°C. The reaction was carried out for seven days. After the in-vitro test, the BG, SiC fiber, and SBF reaction solution were filtered through a polytetrafluoroethylene filter. The remaining residue was dried in a desiccator for one day.

2.4. Analysis of the microstructure and crystalline phases

The microstructure and composition of the 13-93 BG and SiC fibers that reacted with the SBF solution were confirmed by scanning electron microscopy (SEM; JSM-6390, JEOL, Japan) and energy dispersive spectrometry (EDS; AZtecOne, Oxford Instruments, UK). X-ray diffraction (XRD; D/MAX-2500/PC, Rigaku, Japan) analysis was also performed to confirm the substances produced. The measurement conditions were an acceleration voltage of 40 kV, a scan speed of 5°/min, and a range of 10° to 80°.

3. Results and Discussion

The change in the diameter of the 13-93 BG fiber according to the winding force and number of rotations is shown in Fig. 2. It was assumed that the amount of melt glass discharged through the nozzle would remain constant. As expected, the average glass fiber diameter decreased with increasing winding force and number of rotations. The fiber diameter is related to the winding force and number of rotations, and is expressed by the following regression equations:

$$D = 36.996 - 0.125 F + 0.000143 F^2 \quad (R^2_{(adj)} = 0.97249) \quad (1)$$
$$D = 41.152 - 0.214 \text{RPM} \quad (R^2_{(adj)} = 0.9669) \quad (2)$$

where $D$ is the fiber diameter, $F$ is the winding force, and RPM is the number of rotations.

The large $R^2_{(adj)}$ for the two equations suggest their reliabilities are very high. The required diameter of the BG

fiber can be obtained by adjusting the winding force and number of rotations.

In an attempt to continuously draw fibers, the glass viscosity was measured at 1295°C, which had been experimentally determined through trial and error. In general, the viscosity of glass tends to decrease when its temperature exceeds \( T_g \). The viscosity dependence of the glass temperature at high temperatures follows Arrhenius behavior, but the activation energy for viscous flow is not constant. Therefore, the viscosity of the glass was calculated by using the Vogel-Fulcher-Tamman (VFT) equation (eq. 3).

\[
\log \eta = A + \frac{B}{(T - T_0)} \quad (3)
\]

Here, \( A, B, \) and \( T_0 \) are constants. These three constants can be calculated by using the reference points \((T_g, T_{dsp}, T_{1/2})\) in the VFT equation, and the results are as follows.

\[
\log \eta = 1.79 + \frac{1192.15}{(T - 481.29)} \quad (4)
\]

The viscosity value corresponding to the temperature of 1295°C was \( \eta = 10^{4.25} \) dPa·s. This is higher than \( 10^{2.5} - 10^{3.5} \) dPa·s, which is known as the ideal viscosity range for continuous fiber drawing. On the other hand, in Vedel’s VFT curve\(^7\) for 13-93 BG, 1295°C corresponds to a viscosity lower than \( 10^2 \) dPa·s. It is considered that a separate study on the difference in the viscosity values is needed.

Fig. 6. Scanning electron microscopy and energy dispersive spectrometry analysis of 13-93 BG fiber with in-vitro test in SBF solution for 7 days.
Figure 3(a) shows that the tensile strength increased with decreasing glass fiber diameter. The tensile strength was the highest at 852 MPa when the average fiber diameter was 10–15 μm. The increased strength is considered to be due to the lowered probability of BG surface defects. Fig. 3(b) suggests that the 13-93 BG and SiC fibers were woven at an interval of 2 mm and that the fabric was very flexible. According to Hooke’s Law (δ = PL/AE), when an elastic body is subjected to an external force beyond its elastic limit, its deformation becomes larger with decreasing cross-sectional area. Therefore, the BG prepared as fibers can be processed into highly flexible fabrics.

The results of the measurement of the tensile strength of the BG-SiC fiber-bundle composite are displayed in Fig. 4. The number of SiC fibers affected the tensile strength. In particular, when one SiC fiber was substituted, the tensile strength was 1428 MPa, which was 81% higher than that of a bundle consisting of BG fibers alone. The strength of the fiber-bundle composite with 6 SiC fibers increased rapidly to 2342 MPa. The tensile strength of single fibers and bundles were measured to be 796 MPa and 787 MPa, respectively, for BG and 2838 MPa and 2858 MPa, respectively, for SiC. Since 1 Pa = 1 N/m², the mechanical properties of each fiber do not change as the area increases from a single fiber to a bundle, whereas forces are acting simultaneously. Therefore, the BG-SiC fiber-bundle composite material is effective in improving the strength, since stress dispersion occurs in the SiC fiber.

Figure 5 and 6 show the surface changes after in-vitro testing of the BG-SiC fabric composite with a SBF solution for seven days. Fig. 5 shows the reaction of the SBF solution with the SiC fiber. The surface of the SiC fibers that reacted for seven days was kept clean. This represents the inherent bio-reactivity of the bio-inert SiC fibers. According to the in-vitro test of the BG-SiC fabric composite, it is expected that the SiC fiber will play a role in maintaining the strength of the BG-SiC fabric composite.

Figure 6 displays the reaction of the SBF solution with the 13-93 BG fibers. In the case of the 13-93 BG fiber reacting with the solution for one day, a layer with a high content of silica was formed on the surface and cracks occurred. This is because the reaction with the solution elutes the network modifier to form a SiO₂-rich layer that shrinks due to the residual stress. After 3 days, small particles are visible as reaction products on the surface. There was no significant difference in the components of the BG fibers reacted for 1 day and 3 days. This is because the SBF solution component is already present within the 13-93 BG, and the reactivity is slow due to the high SiO₂ content. After 5 days of BG fiber reaction, a full-scale change occurred. The alkaline earth ions that had been eluted with the solution began to deposit again on the surface. The particles grew into reactive substances containing high concentrations of Ca and P. After 7 days, the particles became coarser and the Si concentration was very low compared to those of Ca and P. In addition, the delamination of the silica-rich layer further increased compared to that observed at the beginning of the reaction. This can be attributed to an increase in the reaction time between the BG fiber and the SBF solution. BG is transplanted into the human body, and various ions such as Ca²⁺, P⁵⁺, and Na⁺ are released from its surface. Network modifiers, such as Na⁺ and Ca²⁺, form weak bonds with nonbridging oxygens, and hence, their leaching rates are very high. Some studies have shown that the negative surface potential of the hydroxyl groups present on the surface of the BG fibers attracts the Ca²⁺ existing in the solution, resulting in the formation of an amorphous Ca-related oxide and generation of a positive surface potential. It is known that phosphorous ions are attracted to form amorphous calcium phosphate (ACP) on the SiO₂ layer of the glass surface. Then, the ACP is crystallized and grown as a hydroxycarbonate apatite (HCP) crystal.

The 13-93 BG fiber and SiC fiber were reacted in the SBF solution for 7 days, and the results of crystalline phase anal-

---

ysis of the reactants are shown in Fig. 7. In the case of 13-93 BG fibers, 3 days after the reaction, a crystalline phase peak was observed at 2θ = 14° and a hollow peak at 2θ = 20° to 30°. The particles formed on the BG fiber surface were the crystalline phase of calcium phosphate hydrate. After 5 days, many calcium phosphate hydrate crystals were formed on the surface and the peak intensity increased. Unlike the mechanism proposed by Hench, the calcium phosphate crystalline phase was produced, and not ACP or HCP. On the other hand, no product formed on the SiC fiber. Therefore, when the BG-SiC fabric composite is transplanted into the body, it is expected that the SiC fiber remains in the transplantation site and maintains the strength, even though BG is dissolved due to the biological reaction.

4. Conclusions

In the present study, BG-SiC fabric composites were prepared and changes in the mechanical properties were confirmed. In addition, an in-vitro test was carried out with SBF solution and the biocompatibility analyzed.

The 13-93 BG-SiC fiber-bundle composites showed an increase in strength that was in proportion to the number of SiC fibers replaced in the bundle, and the tensile strength was 81% higher than that of BG fiber-bundles, even when only one SiC fiber was substituted. The 13-93 BG-SiC fabric composite, which is highly flexible beyond its elastic limit, is expected to provide toughness. As a result of the in-vitro test, a silica-rich layer was formed on the 13-93 BG fiber surface. Damage to the fiber surface was inevitable due to the reaction with the solution. Furthermore, over time, calcium phosphate began to form on the silica-rich layer of the BG fiber, while the SiC fiber maintained the initial state. When the BG-SiC fabric composite is transplanted into the human body, its strength will be maintained owing to the bio-inert nature of the SiC fibers.
